Project Starting Date: July, 2000

Projected Completion Date: March, 2003

1. Introduction

Animal by-product meals are a significant source of several nutrients that are of value to the commercial poultry industry. These include protein and energy. The value of these products is based on the availability of these nutrients in the animal protein meals. Very little information on the available energy content of these meals for utilization by poultry has been collected. Due to this many nutritionists will place relatively low values on energy to avoid the potential for underfeeding of this important nutrient. Determining the correct metabolizable energy values for various by-products will increase the apparent value of these by-products for poultry rations.

Use of by-products in rations for poultry has the potential to improve utilization of rendered products. Each 1% increment of rendered by-product use would use as much as 75,000 tons of rendered product in the turkey industry alone. If an increase in the metabolizable energy content of these meals could be demonstrated, a substantial increase in use could occur.

2. Objectives:

To determine the energy availability of different animal by-product sources for turkeys and broilers.

3. Industry Summary

This project was designed to determine the energy availability of different animal by-product sources for turkeys and broilers. Energy analysis of 12 samples of meat and bone meal and 15 samples of poultry by-product meal were conducted using turkeys, broilers and the leghorn rooster as the research animals. Each sample will be analyzed in three different fashions (Zanella et al., 1999). The first of these will be the commonly used True Metabolizable Energy (TME) analysis based on the work of Sibbald (1986) and slightly modified for use in intact turkeys and caecectomized roosters. Briefly, birds will denied access to feed for 36 hrs to clear the gut by being placed in digestibility cages. Each bird (8 replicates) will then be tube fed a quantity of feed equal to approximately 2% of body weight. Feces will then be collected for 48 hrs post feeding. In addition, endogenous feces will be collected from a similar group of birds at the same time with all procedures identical with the exception of the tube feeding. The energy from these feces will be used to correct for fecal energy that would have been excreted regardless of the feed sample being fed. Both feed energy in and fecal energy out (corrected for endogenous loss) will be measured by bomb calorimetry and TME calculated from the difference of these numbers. In the second series of experiments, a modified total collection will be done for determination of Apparent Metabolizable Energy (AME) and a longer term TME valuation. In these experiments, 3 wk old birds will be fed a basal diet and energy value determined. This basal diet will then be diluted (50%) by addition of the products being tested. Birds will be fed for 3 days on the test diet with total feed intake measured as well as total feces collection. Energy determination of feed and feces adjusted for the energy content of the basal ration will be used to determine AME. In a modification of this procedure, birds will be pulled from feed at both the beginning and end of the trial for 24 hrs and endogenous excreta collected for a 24 hr period on day 1 and 3 of the trial. Endogenous loss will be estimated from these birds for the entire collection period and used for adjustment of the AME values. A minimum of 6 pens of birds will be used for each feed determination. The third method will be based on ileal digesta contents. Cromic oxide will be added to diets at .05% of the diet. Poulets being fed the test diets will be killed with CO₂ and ileal contents collected from Meckels diverticulum to the ileocolic juncture. Energy will be determined by the differences between cromic oxide concentration in

diet and digesta. All data were analyzed for differences due to procedure as well as samples within procedures.

Results of the project are found in the attached tables. Briefly, poultry meal samples ran at book values or somewhat lower. This is primarily due to the increased ash content and decreased fat content found in certain meals. Meals from many plants are showing changes in composition based on the carcass inclusion in the product. This is due to further processing of the chicken versus whole bird production of the past. The variety of assay methodologies utilized showed few differences (11 of 15 were similar) between procedures, indicating that any of the methods used are acceptable. This is as would be expected as each of the procedures should provide similar results. There was a tendency for turkey values to be slightly lower although statistical differences were not found.

Meat meal samples ran at book values or above. Improved processing procedures have probably improved digestibility in the recent past. Differences in procedure were found within samples in some cases. Generally this was manifested in lower values for chick digesta AME's. Chick and turkey values for meat meal samples were very similar within samples.

Overall it appears that any energy analysis method is acceptable, although there were more differences in meat meal samples than in poultry meal samples. There were also few differences between chickens and turkeys in these samples.

Abstract

This project was designed to determine the energy availability of different animal by-product sources for turkeys and broilers. Energy analysis of 12 samples of meat and bone meal and 15 samples of poultry by-product meal were conducted using turkeys, broilers and the leghorn rooster as the research animals. Each sample will be analyzed in three different fashions (Zanella et al., 1999). The first of these will be the commonly used True Metabolizable Energy (TME) analysis based on the work of Sibbald (1986) and slightly modified for use in intact turkeys and cecectomized roosters. Briefly, birds will be denied access to feed for 36 hrs to clear the gut by being placed in digestibility cages. Each bird (8 replicates) will then be tube fed a quantity of feed equal to approximately 2% of body weight. Feces will then be collected for 48 hrs post feeding. In addition, endogenous feces will be collected from a similar group of birds at the same time with all procedures identical with the exception of the tube feeding. The energy from these feces will be used to correct for fecal energy that would have been excreted regardless of the feed sample being fed. Both feed energy in and fecal energy out (corrected for endogenous loss) will be measured by bomb calorimetry and TME calculated from the difference of these numbers. In the second series of experiments, a modified total collection will be done for determination of Apparent Metabolizable Energy (AME) and a longer term TME valuation. In these experiments, 3 wk old birds will be fed a basal diet and energy value determined. This basal diet will then be diluted (50%) by addition of the products being tested. Birds will be fed for 3 days on the test diet with total feed intake measured as well as total feces collection. Keywords: Poultry , turkey, broiler, energy, meat meal, poultry meal

Introduction

Animal by-product meals are a significant source of several nutrients that are of value to the commercial poultry industry. These include protein and energy. The value of these products is based on the availability of these nutrients in the animal protein meals. Very little information on the available energy content of these meals for utilization by poultry has been collected. Due to this many nutritionists will place relatively low values on energy to avoid the potential for underfeeding of this important nutrient. Determining the correct metabolizable energy values for various by-products will increase the apparent value of these by-products for poultry rations.

Use of by-products in rations for poultry has the potential to improve utilization of rendered products. Each 1% increment of rendered by-product use would use as much as 75,000 tons of rendered product in the turkey industry alone. If an increase in the metabolizable energy content of these meals could be demonstrated, a substantial increase in use could occur.

The ME and TME systems have been in place for a number of years and are widely used. In the future we may move to net energy systems as a more accurate method of estimating actual energy use by the bird for productive purposes, but this will not happen in the foreseeable future. In the realm of turkey nutrition, there have been few trials to determine the ME or TME content of feeds for turkeys. Most of the energy data has been used based on the broiler or the TME system with the Leghorn rooster (Sibbald, 1986). Analysis of feedstuffs used in our lab have shown significant differences in digestibilities of amino acids as well as energy values between commonly used book values and determined values in turkeys. Determined energy values of corn and soybean meal were lower in ducks than values found in chicken assays (Farhat et al., 1998) which implies that species differences may occur. Ostrowski-Meissner (1984) also reported differences between species. While there is substantial discussion in the literature about correct methodology for energy determinations, it appears that the original TME procedure of Sibbald (1987) is well accepted and that the total collection method of AME determination may be more accurate than the ileal digesta method (Scott et al., 1998) although this can be easily disputed (Zanella et al., 1999). These data should prove useful to the commercial poultry industry.

The objective of these studies was to determine the energy availability of different animal by-product sources for turkeys and broilers.

Procedures

Energy analysis of 12 samples of meat and bone meal and 15 samples of poultry by-product meal were conducted using turkeys, broilers and the leghorn rooster as the research animals. Each sample will be analyzed in three different fashions (Zanella et al., 1999). The first of these will be the commonly used True Metabolizable Energy (TME) analysis based on the work of Sibbald (1986) and slightly modified for use in intact turkeys and cecectomized roosters. Briefly, birds will denied access to feed for 36 hrs to clear the gut by being placed in digestibility cages. Each bird (8 replicates) will then be tube fed a quantity of feed equal to approximately 2% of body weight. Feces will then be collected for 48 hrs post feeding. In addition, endogenous feces will be collected from a similar group of birds at the same time with all procedures identical with the exception of the tube feeding. The energy from these feces will be used to correct for fecal energy that would have been excreted regardless of the feed sample being fed. Both feed energy in and fecal energy out (corrected for endogenous loss) will be measured by

bomb calorimetry and TME calculated from the difference of these numbers. In the second series of experiments, a modified total collection will be done for determination of Apparent Metabolizable Energy (AME) and a longer term TME valuation. In these experiments, 3 wk old birds will be fed a basal diet and energy value determined. This basal diet will then be diluted (40%) by addition of the products being tested. Birds will be fed for 3 days on the test diet with total feed intake measured as well as total feces collection. Energy determination of feed and feces adjusted for the energy content of the basal ration will be used to determine AME. In a modification of this procedure, birds will be pulled from feed at both the beginning and end of the trial for 24 hrs and endogenous excreta collected for a 24 hr period on day 1 and 3 of the trial. Endogenous loss will be estimated from these birds for the entire collection period and used for adjustment of the AME values. A minimum of 6 pens of birds will be used for each feed determination. The third method will be based on ileal digesta contents. Cromic oxide will be added to diets at .05% of the diet. Poult's being fed the test diets will be killed with CO₂ and ileal contents collected from Meckels diverticulum to the ileocolic juncture. Energy will be determined by the differences between cromic oxide concentration in diet and digesta. All data were analyzed for differences due to procedure as well as samples within procedures.

Results

Results for the experiments are presented in the attached tables. Statistical analysis output has also been provided. Poultry meal samples ran at published values or somewhat lower. The variety of assay methodologies utilized showed few differences (12 of 15) between procedures, indicating that any of the methods used are acceptable. This is as would be expected as each of the procedures should provide similar results. There was a tendency for turkey values to be slightly lower although statistical differences were not found.

Meat meal samples ran at published values or above. Improved processing procedures have probably improved digestibility in the recent past. Differences in procedure were found within samples in some cases. Generally this was manifested in lower values for chick digesta AME's. Chick and turkey values for meat meal samples were very similar within samples indicating that broiler or Leghorn rooster values would be acceptable for use in all species.

Discussion

Relatively little work has been done to evaluate the energy content of rendered poultry and meat meals. This study shows that a variety of different analytical methods can be used with similar results. While there have been arguments amongst scientists about analytical methodology, when looked at critically, each of the methods should yield similar results. For example, the standard AME procedure has been criticized as it does not account for endogenous losses as are done in the TME. However, if one feeds sufficient feed, the relative proportion of endogenous loss (which is high in the precision fed assay) becomes quite small and induces little variation as determined by these data.. Thus it can be concluded that all analytical methods are probably acceptable and should be used as appropriate to the conditions available.

Energy contents of meat meal were generally higher than those found by Martosiswoyo and Jensen in 1988, but similar to values determined more recently (Dale, 1997). This may be due to improved process control methods. Energy content of poultry meal samples were similar to below book values. This is a reflection of some of the higher ash contents seen more recently in poultry meals. Dale and coworkers (1993) found average energy values of poultry meals to be

over 4600 kcal/kg. However, these were very low ash content samples with fat content averaging over 32%.

Another area of concern is the use of energy values collected from different types/species of birds. Firman and Remus (1993) showed that there are some species differences and the reader should be cautioned that although there were no differences seen with these feedstuffs, other feedstuffs have been shown to differ in energy content between species.

Conclusions

1. Overall it appears that any energy analysis method is acceptable, although there were more differences in meat meal samples than in poultry meal samples.
2. There were also few differences between chickens and turkeys in these samples.
3. Energy content of some meat meal samples were higher than older published values.
